Abstract

The patient was a 24-year-old woman with a history of depression and panic disorder. She attempted to commit suicide by burning charcoal in a sealed bathroom by placing charcoal on a steel mesh grate and igniting it from the bottom using a barbecue stove. The bathroom was filled with white smoke. After experiencing dyspnea, she opened the door of the bathroom and telephoned a friend who called an ambulance. She was transported to a local hospital by the ambulance. On arrival, she showed mild consciousness disturbance. A physiological examination revealed no specific findings. Thoracic computed tomography showed a diffuse patchy ground glass appearance. The results of an arterial blood gas analysis revealed carboxyhemoglobinemia and methemoglobinemia. She was diagnosed with carbon monoxide poisoning, methemoglobinemia and chemical lung edema. She was transferred to another hospital for hyperbaric oxygen therapy. After 5 days of hyperbaric oxygen therapy, she was discharged without sequelae.

The present report shows extremely rare combination of carbon monoxide poisoning, methemoglobinemia and lung edema after a suicide attempt in which an individual burned charcoal on a steel mesh grate. Physicians should pay attention to the burned materials and the systemic condition of the patient when treating patients who have inhaled smoke from burning materials.

Keywords: Pulmonary Edema; Methemoglobinemia; Charcoal; Suicide

Introduction

A report from the Ministry of Health, Labour and Welfare regarding suicides in the Heisei 27 fiscal year (nearly 2015) showed that hanging was the most common method of suicide employed by males, followed by charcoal burning, while hanging followed by falling, drowning and charcoal burning were the most common methods of suicide employed by females [1]. Charcoal burning is a common suicide method in Asian countries, but is rare in the West [2]. Charcoal burning suicide, which involves burning charcoal in a sealed room, causes death by carbon monoxide poisoning. We herein report a case in which a patient developed lung edema and methemoglobinemia after attempting suicide by burning charcoal on a steel mesh grate.

Case Presentation

The patient was a 24-year-old woman with a history of depression, panic disorder and attempted suicide by hanging, who was treated with paroxetine and zolpidem. She attempted to commit suicide by burning charcoal in a sealed bathroom by placing some charcoal on a steel mesh grate and igniting it from the bottom using a barbecue stove (Figure 1).

Figure 1. The barbecue stove in the bathroom. The patient placed the charcoal on a steel mesh grate and ignited them from the bottom using the barbecue stove.

The bathroom was filled with white smoke. After experiencing dyspnea, she opened the door of the bathroom and telephoned a friend who called an ambulance. Hydrogen sulfate gas was not detected when firefighters checked her room using a gas-detecting tube. No chlorine detergent was found in the bathroom. She was transported to Numazu City Hospital with 15 L per minute of oxygen mask by the ambulance. On

arrival, her vital signs were as follows: Glasgow Coma Scale, E3V5M6; blood pressure, 98/50 mmHg; heart rate, 64 beats per minute; respiratory rate 30 breaths per minute; body temperature, 36.3°C. A physiological examination, electrocardiography and chest roentgenography revealed no specific findings.

Whole-body computed tomography showed a diffuse patchy ground glass appearance (Figure 2). The results of an arterial blood gas analysis, cell blood count and biochemical study are shown in Table 1. She was diagnosed with carbon monoxide poisoning, methemoglobinemia and chemical lung edema. She was transferred to Shizuoka Saiseikai General Hospital for hyperbaric oxygen therapy in a multiplace chamber. After 5 days of hyperbaric oxygen therapy with 3 atmospheres of absolute pressure, she was discharged without sequelae.

Figure 2. Thoracic computed tomography (CT) on arrival. CT shows a diffuse patchy ground glass appearance.

Table 1. The Results of the Laboratory Analysis

Arterial blood gas (15 L/minute oxygen)			
pH	7.396	PCO ₂	43.2 mmHg ₂
PO ₂	422.5 mmHg	HCO ₃ ⁻	25.9 mmol/l
Base excess	1.1 mmol/l	Lactate	11.0 mmol/l
Carboxyhemoglobin	14.50%	Methemoglobin	11.10%
Blood count			
White blood cell count	7100 /μl	Hemoglobin	10.9 g/dl
Platelet count	23.7 × 10 ⁴ /μl		
Serum biochemistry			
Total protein	6.2 g/dl	Total bilirubin	0.6 mg/dl
Aspartate aminotransferase	16 IU/l	Alanine aminotransferase	9 U/l
Lactate dehydrogenase	178 IU/L	Alkaline Phosphatase	120 IU/L
Blood urea nitrogen	14.7 mg/dl	Creatinine	0.60 mg/dl
Sodium	139 mEq/l	Potassium	3.7 mEq/l
Chloride	103 mEq/l	C reactive protein	0.02 mg/dl

Discussion

We performed a PubMed search on June 20, 2020 using the following key words: carbon monoxide poisoning or carboxyhemoglobinemia, methemoglobinemia and lung edema. The search revealed no previous reports in which these three complicating conditions were present simultaneously. This might be the first reported case in which attempted suicide by burning charcoal on a steel mesh grate was associated with carbon monoxide poisoning, methemoglobinemia and lung edema. Accordingly, we discuss the mechanism underlying the development of methemoglobinemia and lung edema.

The incomplete combustion of burning charcoal can produce carbon dioxide and carbon monoxide. The burning of iron burning, it can produce various iron oxides, including Fe₃O₄, Fe₂O₃, and 2FeO. The inhalation of iron oxide particles containing soluble iron can induce mild pulmonary inflammation and lead to altered alveolar epithelial integrity and altered gas exchange [3, 4]. Accordingly, the lung edema in the present case was thought to have been induced by the inhalation of iron oxide particles, which were produced by the burning of the steel mesh grate in the sealed bathroom. Another possible mechanism through which lung edema may form is hypoxia-induced lung edema [5, 6]. Intrapulmonary arteries constrict in response to alveolar hypoxia, diverting blood to better-oxygenated lung segments, thereby optimizing the supply of oxygen [6]. However, this induces an increase in the pulmonary artery pressure. The rapid increase in pulmonary artery pressure stresses and distends the arterial walls. Within a short time, these changes exceed the load capacity of the pulmonary artery resistance, resulting in the rupture of the basement membrane and the alveolar-capillary barrier, and the formation of lung edema [6]. However, hypoxia-induced lung edema is associated with diffuse edema. In contrast, the lung edema in the present case appeared as edema in each bronchiole segment, which was compatible with lung edema induced by the inhalation of iron oxide particles. Accordingly, in the present case, we consider the possibility of hypoxia-induced lung edema to be minimal. Cui et al reported that rats develop lung edema, hemorrhage, and inflammatory cell infiltration after inhaling white smoke from a burning smoke pot [7]. Accordingly, physicians should pay attention to the burned materials and systemic condition of the patient when treating patients who have inhaled smoke from burning materials.

Methemoglobin is formed by the oxidation of ferrous (FeII) heme to the ferric (FeIII) state; the mechanisms through which this occurs are complex. Most cases are due to one of three processes [8]. The first mechanism involves the direct oxidation of ferroheme, which involves the transfer of electrons from ferrous heme to the oxidizing compound. This mechanism proceeds most readily in the absence of oxygen [8]. The second mechanism involves indirect oxidation, a process of co-oxidation that requires hemoglobin-bound oxygen and which is involved, for example, in nitrite-induced methemoglobinaemia [8]. The third mechanism involves the biotransformation of a chemical into an active intermediate that initiates methemoglobin formation by

a variety of mechanisms. This is the means by which most aromatic compounds, such as amino- and nitro-derivatives of benzene, produce methemoglobin [8]. In cases involving fire, methemoglobinemia has been reported to have been caused by the inhalation of hydrogen cyanide liberated from burning plastics [9]. In the present case there was no evidence of exposure to nitrite, amino- and nitro-derivatives of benzene, or burning plastics. Accordingly, hypoxia and/or ionized iron oxide may have contributed to the development of methemoglobin in the present case.

Hyperbaric oxygen therapy is a useful treatment for patients with carbon monoxide poisoning, as well as those with methemoglobinemia [10, 11] and may be useful for lung edema under specific conditions [12-14]. However, hyperbaric oxygen therapy itself can induce lung edema [15, 16]. Accordingly, the physician should pay attention to the general physical condition during hyperbaric oxygen therapy for patients with lung edema.

Conclusion

The present report shows an extremely rare combination of carbon monoxide poisoning, methemoglobinemia and lung edema after a suicide attempt in which an individual burned charcoal on a steel mesh grate. Physicians should pay attention to the burned materials and the systemic condition of the patient when treating patients who have inhaled smoke from burning materials.
